A 61-year-old man presented with a 1.4×1.4-cm soft, pink, papillomatous, ulcerated nodule on his left perianal area of 3 years’ duration. The lesion would bleed when irritated.
Syringocystadenoma papilliferum (SCAP) is an uncommon tumor of sweat gland origin.\textsuperscript{1,2} Although approximately half of these tumors are present at birth, they can appear at any time later in life.\textsuperscript{2,3} Syringocystadenoma papilliferum can arise de novo, but in 40% of cases, it is associated with nevus sebaceus.\textsuperscript{3}

The clinical presentation of SCAP is not distinctive. It can present as a solitary patch, papule, plaque, or nodule (Figure 1),\textsuperscript{2} or as several papules often arranged linearly.\textsuperscript{4-6} Its color varies and may be flesh colored, pink, red, brown, or gray.\textsuperscript{2,4} Its surface may be smooth, hyperkeratotic, verrucous, papillary, or moist and fleshy. The tumors tend to grow slowly and usually are less than 4 cm in size.\textsuperscript{2} Occasionally, they are pedunculated or umbilicated and even exude fluid or keratinous debris from a central pore.\textsuperscript{2,7} Syringocystadenoma papilliferum may be pruritic or ulcerate and bleed with irritation.\textsuperscript{2} It is located on the head and neck 75% of the time but also has been reported on the extremities and trunk, including the groin, buttocks, and gluteal fold.\textsuperscript{2,3,8}

Although its clinical presentation is variable, SCAP can be distinguished histologically by its ductlike structures with irregular papillary projections, invaginating from the surface epithelium into the underlying dermis, sometimes forming cystic cavities (Figure 2). The ductlike structures are lined by stratified squamous epithelium near the epidermal surface, transitioning to a double-layered epithelium below.\textsuperscript{2} The 2 layers consist of an inner luminal layer of columnar cells with some evidence of decapitation secretion, resting on an outer basal layer of cuboidal cells.\textsuperscript{2,7} The surrounding stroma contains an inflammatory infiltrate composed predominantly of plasma cells (Figure 3). The surface of the lesion may show hyperkeratosis, parakeratosis, acanthosis, and papillomatous changes. Sweat glands usually are present beneath the lesion.\textsuperscript{2} The histogenesis of SCAP is controversial, with evidence supporting apocrine, eccrine, apoeccrine, and pluripotent appendageal cell origin.\textsuperscript{1,2,6}

The differential diagnosis of SCAP is broad. It includes nevus sebaceus, hidradenoma papilliferum, molluscum contagiosum, verruca vulgaris, squamous cell carcinoma, keratoacanthoma, and basal cell carcinoma.

Syringocystadenoma papilliferum is treated by excision.\textsuperscript{2} Rapid growth, pain, ulceration, or bleeding in a long-standing lesion may indicate malignant
transformation to the rare syringocystadenocarcinoma papilliferum. Cases of SCAP associated with basal cell carcinoma have been reported, but they all coexisted with nevus sebaceous.
