When fecal flora ascend via the urethra from the vagina and perineum to the bladder, the bladder mucosa and urethra may become inflamed, leading to urinary tract infection. The most commonly involved pathogens are *Escherichia coli*, *Staphylococcus saprophyticus*, *Klebsiella pneumonia*, and *Proteus mirabilis*.
Urinary tract infections (UTIs) are prevalent among women, afflicting as many as 60% of women during their lifetime.1 Symptoms include urgency, frequency, and dysuria. Although the diagnosis can be made on the basis of symptoms alone in many cases, urinalysis and urine cultures often are helpful in confirming it.2 The differential diagnosis includes infectious or atrophic vaginitis, urethritis from a sexually transmitted infection, urethral diverticulum, painful bladder syndrome, urinary tract calculi, and urinary tract neoplasms. Common risk factors for UTIs are listed in TABLE 1.3

Recurrent UTIs are defined as three infections in 12 months or two infections in 6 months. In this Update, we explore strategies to prevent recurrent UTIs in three groups of women:
- sexually active premenopausal women
- postmenopausal women
- women undergoing pelvic surgery.

In the process, we summarize the results of five trials that explore treatment modalities such as prophylactic antibiotics, vaginal estrogen therapy, cranberry supplementation, and probiotics (TABLE 2, page 48).

CONTINUED ON PAGE 48
UTIs typically involve fecal flora that colonize the vagina and perineum, most commonly *Escherichia coli*, *Staphylococcus saprophyticus*, *Klebsiella pneumonia*, and *Proteus mirabilis*. These pathogens ascend to the bladder via the urethra. Sexual intercourse is thought to facilitate this process, and recurrent UTIs in premenopausal women are often postcoital in temporal pattern.

Daily antibiotic prophylaxis for 6 to 12 months has proved to be effective in the prevention of recurrent UTIs, reducing the risk of recurrence by 95%, compared with placebo.4

In this trial by Melekos and colleagues, sexually active premenopausal women who had a history of three or more documented UTIs in the preceding 12 months were randomly assigned to:

- oral ciprofloxacin, one dose daily, or
- oral ciprofloxacin, one dose immediately after intercourse.

* Consider trimethoprim (100 mg) alone if the patient has an allergy to sulfa.

** Creams are preferred to the vaginal ring or tablets because they can be applied to periurethral tissues.
A total of 135 patients (65 in the daily group and 70 in the postcoital group) were followed for 12 months. The regimens were equally effective at preventing UTIs. The mean number of UTIs in 12 months decreased significantly in both groups—from 3.74 to 0.031 in the daily group and from 3.67 to 0.043 in the postcoital group.

**Fast Track**

Catheterization remained an independent risk factor for UTI after adjusting for other confounding factors.

**What this evidence means for practice**

Postcoital antibiotic prophylaxis is an effective strategy for the prevention of UTIs associated with sexual intercourse in premenopausal women. Although the optimal duration of such a regimen was not addressed in this study, it would be appropriate to revisit the need for prophylaxis after 1 year.

Is there a role for antibiotic prophylaxis among patients who are catheterized following pelvic surgery?

Urinary tract catheterization and urogynecologic surgery are associated with an increased risk for UTI. The risk of UTI following a midurethral sling procedure, in particular, ranges from 4.1% to 33.6% in the literature. To further explore the risk of UTI after placement of a midurethral sling, Dieter and colleagues followed 138 women who had undergone the procedure with and without concomitant pelvic surgery. The primary outcome was treatment of UTI within the first 3 weeks postoperatively.

Catheterization increased the risk of UTI

Fifty-eight percent of women required placement of a catheter postoperatively—either an indwelling Foley or intermittent self-catheterization. The duration of catheterization ranged from 1 to 14 days, with a mean of 4 days. The incidence of UTI was significantly higher in the group that was catheterized postoperatively, compared with the group that was not (30.0% vs 5.2%), and catheterization remained an independent risk factor for UTI after adjusting for other confounding factors.

Data may not be applicable to other types of surgery

This large retrospective cohort study of a well-characterized population was based on consistent postoperative data related to

**The best antibiotic? Nitrofurantoin or trimethoprim-sulfamethoxazole**

This randomized, controlled trial was rigorous and well-executed and included only healthy premenopausal women. However, given the emergence of antibiotic resistance since this trial was conducted, ciprofloxacin is not an ideal antibiotic for prophylaxis.

Both the American Urological Association and the Infectious Disease Society of America recommend that fluoroquinolones be avoided, if possible, in the treatment of uncomplicated UTIs. A better therapeutic choice would be nitrofurantoin or trimethoprim-sulfamethoxazole.
28% of participants discontinued vaginal estrogen; mild local reactions were the reason.

28% of participants discontinued vaginal estrogen; mild local reactions were the reason.

Vaginal estrogen prevents recurrent UTIs among postmenopausal women

The tissues of the vagina, urethra, bladder, and pelvic floor musculature all express estrogen receptors. In postmenopausal women, the effects of decreased estrogen on the urinary tract include a rise in the vaginal pH level and decreased colonization with Lactobacillus. These effects predispose this population to an increased risk for UTI. The literature does not support the use of oral estrogen replacement as a therapy for recurrent UTI; however, data suggest that vaginal estrogen replacement may be helpful.

Raz and Stamm conducted their randomized trial of 93 postmenopausal women with a history of recurrent UTIs to elucidate the effects of vaginal estrogen on the risk of UTI. Fifty women were randomly assigned to treatment with intravaginal estradiol cream (0.5 mg nightly for 2 weeks, followed by 0.5 mg twice weekly for 8 months), and 43 women were randomly assigned to placebo (equivalent regimen). Compared with the placebo group, the women treated with estradiol experienced a significantly reduced risk of UTI (0.5 vs 5.9 infections per patient-year), increased lactobacilli on vaginal cultures (61% vs 0%), decreased vaginal pH, and a lower rate of colonization with Enterobacteriaceae species.

Although this rigorous double-blind, randomized, placebo-controlled trial was published 20 years ago, its findings remain significant—and have been corroborated in other studies.

Pros and cons of vaginal estrogen replacement

Raz and Stamm utilized vaginal estradiol; the preparations used most commonly today are conjugated estrogens (Premarin) and estradiol (Estrace). Vaginal estrogen formulations can be expensive. Compliance also can wane over time. This study, in particular, showed a discontinuation rate of 28%; mild...
local reactions were the reason. Although the women who discontinued treatment in this study were included in the final analysis, no subanalysis of these patients was published.

Despite these challenges, local estrogen replacement is generally well-tolerated and, with infrequent dosing (twice weekly), has few contraindications. In fact, local estrogen replacement is one of the most highly effective regimens for UTI prevention among postmenopausal women, who can otherwise be difficult to treat for recurrent UTIs.

Cranberry supplementation may prevent UTIs, but products vary widely

Cranberries have been used for many years in various formulations to prevent UTI, but no definitive mechanism has been established. In theory, cranberries keep bacteria from adhering to the urothelium. In vitro studies have revealed that *Escherichia coli* is prevented from adhering to uroepithelial cells by two components of cranberry—fructose and proanthocyanidins.

In this trial of 150 sexually active women (ages 21–72 years) who had experienced at least two UTIs in the past calendar year, Stothers randomly assigned participants to one of three arms for 12 months:
- placebo tablets and cranberry juice (n = 50)
- cranberry tablets and placebo juice (n = 50)
- placebo tablets and placebo juice (n = 50).

Tablets were taken twice daily, and juice was consumed three times daily. All cranberry juice was organic, unsweetened, and unfiltered and taken in 250-mL servings; cranberry tablets were 1:30 parts concentrated cranberry juice.

The risk of UTI during treatment was reduced significantly in the groups taking cranberry juice compared with placebo. Twenty percent of patients consuming cranberry juice experienced a UTI during treatment, compared with 18% of those taking a cranberry tablet and 32% of those in the placebo group (P < .05). In this study, the annual cost of prophylaxis with cranberry juice was $1,400 per woman, and it was $624 per woman for the cranberry tablets. Compliance was lowest among women consuming cranberry juice, decreasing at times to less than 80%.

Findings are difficult to extrapolate

This randomized, double-blind study demonstrated a significant reduction in the rate of UTI with cranberry supplementation, compared with placebo, among women with a mean age of 40 to 44 years. However, because cranberry preparations, juice, and tablets are not regulated as to the amount and bioavailability of the active ingredient, it is difficult to compare one to another and extrapolate to a particular type of preparation.

This study does highlight the higher rate of noncompliance and cost with cranberry juice, although it was as effective at reducing UTIs as cranberry tablets.

WHAT THIS EVIDENCE MEANS FOR PRACTICE

Cranberry supplementation reduced the risk of UTIs in sexually active women; placebo did not. Cranberry use may be an alternative to postcoital antibiotic prophylaxis; a randomized comparison of these therapies is needed.
Can nonhormonal therapy alter vaginal flora?

Probiotics have been used recently in attempts to prevent recurrent UTI, albeit with very little evidence in the literature. Their effectiveness is plausible due to promotion of healthy vaginal flora.

This study by Stapleton and colleagues enrolled premenopausal women (ages 18–40) with a history of one UTI within the past calendar year and a current, active, uncomplicated UTI. Ninety-nine percent of participants were sexually active. All women were treated with a standard antibiotic regimen for UTI. Seven to 10 days later, participants were randomly assigned to:
- Lactobacillus crispatus vaginal suppository [Lactin-V (Osel)], daily for 5 days and then weekly for 10 weeks (n = 50), or
- placebo (same regimen) (n = 50).

The risk of UTI was 15% among women in the probiotic group, compared with 27% in the placebo group—but this difference was only statistically significant for women who had a higher level of Lactobacillus crispatus vaginal colonization in the treatment group.

Vaginal probiotic formulations may be hard to obtain

The use of probiotics to prevent recurrent UTIs is new and innovative. However, vaginal probiotic formulations are not widely available, and most commercially available oral probiotic formulations are marketed for digestive health—an area where the effects have been studied widely.

In this study, the mean age was 21 years. Given that hypoestrogenization is associated with decreased vaginal colonization with Lactobacillus, an interesting area of future study would be the use of probiotics in postmenopausal women.

Continued investigation of probiotics is warranted, as this approach could help in the treatment of women who have intolerance to antibiotics and is generally considered safe and well-tolerated.
