You have just safely delivered the baby who is quietly resting on her mother’s chest. You begin active management of the third stage of labor, administering oxytocin, performing uterine massage and applying controlled tension on the umbilical cord. There is no evidence of excess postpartum bleeding.

How long will you wait to deliver the placenta?

**Active management of the third stage of labor**

Most authorities recommend active management of the third stage of labor because active management reduces the risk of maternal hemorrhage >1,000 mL (relative risk [RR], 0.34), postpartum hemoglobin levels < 9 g/dL (RR, 0.50), and maternal blood transfusion (RR, 0.35) compared with expectant management.1

The most important component of active management of the third stage of labor is the administration of a uterotonic after delivery of the newborn. In the United States, oxytocin is the uterotonic most often utilized for the active management of the third stage of labor. Authors of a recent randomized clinical trial reported that intravenous oxytocin is superior to intramuscular oxytocin for reducing postpartum blood loss (385 vs 445 mL), the frequency of blood loss greater than 1,000 mL (4.6% vs 8.1%), and the rate of maternal blood transfusion (1.5% vs 4.4%).2

In addition to administering oxytocin, the active management of the third stage often involves maneuvers to accelerate placental delivery, including the Crede and Brandt-Andrews maneuvers and controlled tension on the umbilical cord. The Crede maneuver, described in 1853, involves placing a hand on the abdominal wall near the uterine fundus and squeezing the uterine fundus between the thumb and fingers.3,4

The Brandt-Andrews maneuver, described in 1933, involves placing a clamp on the umbilical cord close to the vulva.5 The clamp is used to apply judicious tension on the cord with one hand, while the other hand is placed on the mother’s abdomen with the palm and fingers overlying the junction between the uterine corpus and the lower segment. With judicious tension on the cord, the abdominal hand pushes the uterus upward toward the umbilicus. Placental separation is indicated when lengthening of the umbilical cord occurs. The Brandt-Andrews maneuver may be associated with fewer cases of uterine inversion than the Crede maneuver.5-7

Of note, umbilical cord traction has not been demonstrated to reduce the need for blood transfusion or the incidence of postpartum hemorrhage (PPH) >1,000 mL, and it is commonly utilized by obstetricians and midwives.8,9 Hence, in the third stage, the delivering clinician should routinely administer a uterotonic, but use of judicious tension on the cord can be deferred if the woman prefers a non-interventional approach to delivery.

**Retained placenta after vaginal birth: How long should you wait to manually remove the placenta?**

For a woman with a neuraxial anesthetic, 20 minutes post–birth of the newborn may be the best time to diagnose retained placenta and consider manual removal.
Beware of placenta accreta spectrum disorder, and be ready to recognize and treat uterine inversion

The retained placenta may prevent the uterine muscle from effectively contracting around penetrating veins and arteries, thereby increasing the risk of postpartum hemorrhage. The placenta that has separated from the uterine wall but is trapped inside the uterine cavity can be removed easily with manual extraction. If the placenta is physiologically adherent to the uterine wall, a gentle sweeping motion with an intrauterine hand usually can separate the placenta from the uterus in preparation for manual extraction. However, if a placenta accreta spectrum disorder is contributing to a retained placenta, it may be difficult to separate the densely adherent portion of the uterus from the uterine wall. In the presence of placenta accreta spectrum disorder, vigorous attempts to remove the placenta may precipitate massive bleeding. In some cases, the acchoucheur/midwife may recognize the presence of a focal accreta and cease attempts to remove the placenta in order to organize the personnel and equipment needed to effectively treat a potential case of placenta accreta. In one study, when a placenta accreta was recognized or suspected, immediately ceasing attempts at manually removing the placenta resulted in better case outcomes than continued attempts to remove the placenta.1

Uterine inversion may occur during an attempt to manually remove the placenta. There is universal agreement that once a uterine inversion is recognized it is critically important to immediately restore normal uterine anatomy to avoid massive hemorrhage and maternal shock. The initial management of uterine inversion includes:

FIGURE 1 Use of the finger tips to guide the uterine wall back to normal anatomy.

Following a vaginal birth, when should the diagnosis of retained placenta be made?

The historic definition of retained placenta is nonexpulsion of the placenta 30 minutes after delivery of the newborn. However, many observational studies report that, when active management of the third stage is utilized, 90%, 95%, and 99% of placenta deliver by 9 minutes, 13 minutes, and 28 minutes, respectively.10 In another observational study, compared with women delivering the placenta < 10 minutes after birth, women delivering the placenta ≥30 minutes after birth had a 3-fold increased risk of PPH.11 Similar findings have been reported in other studies.12-14 Based on the association between a delay in delivery of the placenta and an increased risk of PPH, some authorities recommend that, in term pregnancy, the diagnosis of retained placenta should be made at 20 minutes following birth and consideration should be given to removing the placenta at this time. For women with effective neuraxial anesthesia, manual removal of the placenta 20 minutes following birth may be the best decision for balancing the benefit of preventing PPH with the risk of unnecessary intervention. For women with no anesthesia, delaying manual removal of the placenta to 30 minutes or more following birth may permit more time for the placenta to deliver prior to performing an intervention.
• stopping oxytocin infusion
• initiating high volume fluid resuscitation
• considering a dose of a uterine relaxant, such as nitroglycerin or terbutaline
• preparing for blood product replacement.

In my experience, when uterine inversion is immediately recognized and successfully treated, blood product replacement is not usually necessary. However, if uterine inversion has not been immediately recognized or treated, massive hemorrhage and shock may occur.

Two approaches to the vaginal restoration of uterine anatomy involve using the tips of the fingers and palm of the hand to guide the wall of the uterus back to its normal position (FIGURE 1) or to forcefully use a fist to force the uterine wall back to its normal position (FIGURE 2). If these maneuvers are unsuccessful, a laparotomy may be necessary.

At laparotomy, the Huntington or Haultain procedures may help restore normal uterine anatomy. The Huntington procedure involves using clamps to apply symmetrical tension to the left and right round ligaments and/or uterine serosa to sequentially tease the uterus back to normal anatomy.2,3 The Haultain procedure involves a vertical incision on the posterior wall of the uterus to release the uterine constriction ring that is preventing the return of the uterine fundus to its normal position (FIGURE 3).4,5

Best timing for manual extraction of the placenta

The timing for the diagnosis of retained placenta, and the risks and benefits of manual extraction would best be evaluated in a large, randomized clinical trial. However, based on observational studies, in a term pregnancy, the diagnosis of retained placenta is best made using a 20-minute interval. In women with effective neuraxial anesthesia, consideration should be given to manual removal of the placenta at that time.
