Prevention of Venous Thromboembolism in Department of Veterans Affairs Hospitals

Jerome Herbers, MD, MBA
Susan Zarter, BSN
Department of Veterans Affairs, Office of the Inspector General, Washington, DC.

BACKGROUND: Pulmonary embolism (PE) is the most common preventable cause of death in hospitals, but many patients do not receive proven preventive therapies.

OBJECTIVE: To ascertain the extent to which inpatients received therapies for the prevention of venous thromboembolism (VTE).

DESIGN: Medical records review of a random sample of hospitalized patients, stratified by hospital teaching status.

SETTING: Department of Veterans Affairs (VA) acute-care hospitals.

PATIENTS: Two groups hospitalized ≥48 hours during the year ending March 31, 2007: (1) all 4963 patients older than 74 years with a principal discharge diagnosis of heart failure; and (2) all 1448 patients with any discharge diagnosis of PE.

MEASUREMENTS: Rate of VTE preventive care.

RESULTS: Sixty-three of the 100 randomly selected heart failure patients had adequate anticoagulation, 29 (46%) of whom were taking warfarin for chronic conditions. For patients discharged with a PE diagnosis, records from all 330 nonteaching and 449 (40%) teaching hospital cases were reviewed. Most cases (698; 90%) were excluded because there was only a remote history of PE or the diagnosis was made prior to admission. Thirty-four of the 63 patients (54%) with confirmed in-hospital PE and unequivocal VTE risk factors received appropriate preventive treatment. Thirty of the 66 patients (48%) with missed opportunities for prevention had inappropriate mechanical prophylaxis or inadequate use of anticoagulation.

CONCLUSIONS: In hospitalized veterans with PE or at risk for VTE, missed opportunities for prevention were frequent and included inappropriate or inadequate interventions. Retrospective chart review was an inefficient method for identifying patients with in-hospital PE. *Journal of Hospital Medicine* 2010;5:E21–E25. © 2010 Society of Hospital Medicine.

KEYWORDS: anticoagulants—therapeutic use, guideline adherence, hospitalization, pulmonary embolism—prevention and control, venous thromboembolism—prevention and control.
Patient Populations Methods
We examined compliance with accepted VTE clinical practice guidelines in 2 patient populations. First, the care of patients at risk for developing VTE was evaluated for evidence of appropriate preventive measures. Second, the care of patients who developed PE while hospitalized was evaluated for evidence of preventive therapy prior to the event.

We identified patients discharged from VA acute care hospitals during the period April 1, 2006 to March 31, 2007, excluding patients hospitalized for less than 48 hours. We also excluded hospitalizations of VA patients at military and private hospitals because oversight of the quality of care provided at those facilities is beyond the purview of the Inspector General.

We then defined 2 distinct populations:

1. Medical patients at increased risk for VTE. These patients were identified by: (1) age ≥75 years at the time of admission; and (2) hospitalization with a principal discharge diagnosis of heart failure (International Classification of Diseases, 9th edition ICD-9 code 428). Elderly heart failure patients were chosen because advanced age and heart failure are recognized VTE risk factors, medical inpatients have been identified as being neglected in hospital VTE prevention efforts, and the VA was conducting no systemwide assessment of this aspect of care.

2. Patients with established PE. These patients had any discharge diagnosis of pulmonary embolism and infarction (ICD-9 codes 415.1 or 415.19), but those with the diagnostic code “personal history of venous thrombosis and embolism” (V12.51) were excluded.

Within each population, the discharge date defined an index hospitalization for evaluation. For patients discharged more than once with a qualifying diagnosis during the study period, we analyzed only the most recent hospitalization.

Characterization of Facilities
Hospitals were considered teaching hospitals if they were members of the Association of American Medical Colleges’ Council of Teaching Hospitals and Health Systems (COTH). When COTH membership was through a Veterans Integrated Service Network, hospitals were judged to be teaching hospitals if they had 1 or more close university affiliations and/or management of medical inpatients by house staff.

Patient Selection and Medical Record Review
In order to ensure optimal representation of teaching and nonteaching hospitals, we stratified patients with increased VTE risk and those with diagnosed PE according to hospital teaching status, thereby creating 4 groups:

1. Patients at increased risk for VTE—teaching hospitals;
2. Patients at increased risk for VTE—nonteaching hospitals;
3. PE patients—teaching hospitals;
4. PE patients—nonteaching hospitals.

Within each group we assigned a random number to each patient, ordered the patients by random number, and selected patients sequentially until 50 patients were identified or no further eligible patients were available. For the heart failure patients, we assumed that all were at risk for VTE and required prophylaxis. For the group of patients with established PE, we excluded patients if the diagnosis was made prior to admission or in the first 2 hospital days, if there were no acute signs and symptoms and the diagnosis was chronic PE, or if there were no imaging studies or postmortem findings in support of the diagnosis.

In both groups, we assessed patients’ records for VTE risk factors, evidence of preventive care, and contraindications. We considered pertinent VTE risk factors to be those included with published guidelines. In the care of patients with established PE, designation of adequate prophylactic therapy required at least 24 hours of treatment prior to diagnosis.

Appropriate VTE prophylaxis was defined as anticoagulant medications or, in the case of contraindications to anticoagulation, mechanical compression devices applied to the lower extremities with or without antiembolism stockings. Any administration of warfarin, low–molecular-weight heparin, or heparin by infusion, was considered adequate. Prophylaxis with subcutaneous unfractionated heparin was considered adequate only if at least 5000 units was administered 3 times daily. Aspirin and other antiplatelet agents were not considered to be anticoagulants.

We characterized hospitalizations of at-risk individuals as missed opportunities for prevention if there were no contraindications to treatment and no evidence that adequate prophylactic therapy was provided.

Data Analysis
To determine sample size for each of the 2 study populations, we assumed the baseline rate of compliance with recommendations for VTE prophylaxis among medical inpatients to be 0.4 to 0.5. We further assumed that an observed compliance rate of 0.7 would be indicative of an important difference compared with published results (rate difference, 0.2-0.3). With a Type 1 (alpha) error of 0.025 (1-tailed), approximately 90 patients are required for a 0.9 probability of detecting a difference of at least 0.25.

Comparisons between teaching and nonteaching hospitals were analyzed using chi-square tests. Confidence intervals for estimates of overall compliance were calculated using a normal approximation to the binomial distribution.

Results
Medical Patients at Increased Risk for VTE
We identified 4963 patients age 75 and older discharged after at least 2 days of acute hospitalization for heart failure: 3437 from 73 teaching hospitals and 1526 from 58 nonteaching hospitals. The 100 patients randomly selected for
review ranged in age from 75 to 94 (median, 82) and had hospitalizations of 3 to 41 days (median, 6). Ninety-eight were male. In this group of patients, we found 63 with evidence of adequate pharmacologic VTE prevention and 37 for which opportunities for prevention were not realized. At teaching hospitals, anticoagulation was effected with warfarin (13 cases), heparin (11), and enoxaparin (10). At nonteaching hospitals anticoagulants included warfarin (16), enoxaparin (11), and heparin (2). Twenty-nine of the 63 patients who received anticoagulation (46%) were admitted while taking warfarin for chronic conditions. Teaching and nonteaching hospitals did not differ with respect to missed opportunities for prevention of VTE (37% in each group; Table 1).

**Patients With Established PE**

We identified 1448 acute hospitalizations of at least 2 days duration for patients with PE, 1118 from 72 teaching hospitals and 330 from 51 nonteaching hospitals. We reviewed 779 medical records, 449 (40.2%) teaching cases and all 330 nonteaching cases. Chart review was completed after all nonteaching cases had been reviewed. In only 8.2% (64) of reviewed cases was the diagnosis of acute PE made after the first 2 hospital days and with accompanying objective evidence of VTE. Most cases (698; 89.6%) were excluded because there was only a remote history of PE or the diagnosis was made prior to admission. Additional cases (17; 2.2%) were excluded because the diagnosis was made during the first 2 hospital days; there were no acute signs and symptoms and the diagnosis was chronic PE; or there was no confirmation by computed tomography or ventilation-perfusion scans, lower extremity ultrasonography in the setting of consistent clinical findings, or autopsy.

The 64 patients with confirmed in-hospital PE ranged in age from 44 to 85 years (median, 65) and had hospitalizations of 4 to 53 days (median, 16). Sixty-three were male. One of these patients had no definite risk factors for VTE and was ambulatory when acute symptoms occurred. Among the 63 patients who had unequivocal VTE risk factors, 34 (54%) received appropriate prophylactic treatment, and 29 (46%) received inadequate or no preventive therapy (Table 2). There was no significant difference between teaching and nonteaching hospitals with respect to missed opportunities for prevention (49% vs. 35%; \( P \geq 0.3 \)).

Anticoagulants used at teaching hospitals included heparin (15 cases), enoxaparin (4), and warfarin (1), while at nonteaching hospitals enoxaparin (7) and heparin (3) were used.

Each of the 10 patients who received no anticoagulation had the VTE risk factor of recent immobility prior to PE. Nine of the 10 had active malignancies, and 4 of these had undergone recent surgery. None had evidence of hypercoagulable states (factor V Leiden, lupus anticoagulant, or anticardiolipin antibodies). Five of the 10 patients died in the year following pulmonary embolism, 3 prior to discharge or within 2 weeks of discharge.

**Missed Opportunities for Prevention**

Among the 66 patients whose hospitalizations were characterized as missed opportunities for prevention, 30 received no pharmacologic VTE prevention despite having no contraindications. Seven patients had contraindications to pharmacologic prophylaxis, but none of these patients had contraindications to mechanical prophylaxis. An additional 18 patients received mechanical prophylaxis only despite having no contraindications to anticoagulation. Eleven patients received inadequate heparin regimens with or without mechanical prophylaxis (Table 3).

**Discussion**

Based on a random sample of 4963 elderly heart failure patients admitted to VA hospitals during a 1-year period, we estimated that 63% received recommended interventions aimed at preventing VTE. Although differences in methodology limit comparisons with published reports, this rate is similar to those observed at individual hospitals.

large multicenter registries of patients with DVT or at risk for VTE, and in a recent multinational cross-sectional study. Notably, chronic outpatient anticoagulation that was continued during hospitalization accounted for nearly one-half of patients receiving preventive care. Compliance did not differ between teaching and nonteaching hospitals.

In a complementary approach to examining the extent of preventive care, we identified 1448 patients discharged with a diagnosis of PE. Most of these patients were excluded because they did not have a new event while hospitalized. Eleven (17%) of the 64 patients with confirmed in-hospital PE received no preventive care before the event. An additional 18 (28%) received suboptimal heparin regimens or mechanical prophylaxis in the absence of contraindications to anticoagulation. As with the patients at risk for VTE, patients with established PE at teaching and nonteaching hospitals received similar rates of preventive care. Contrary to our expectation, the observed difference in rates between types of hospitals favored nonteaching hospitals. However, the sample size for this comparison was small and the difference did not reach statistical significance.

This study’s population-based approach permits conclusions about the performance of the VA’s entire system of acute care hospitals. The results indicate that proven preventive therapies are often neglected at VA hospitals, but overall performance is probably comparable to other settings. VA employs an extensively implemented electronic medical record (EMR) and superior performance might have been expected. However, these results suggest limitations in the EMR as it is currently deployed. Successful efforts probably require a multifaceted approach incorporating decision support and institutional standardization.

Several additional findings warrant comment. Patients with malignancies accounted for 9 of 10 patients who had PE after receiving no prior anticoagulation. Recent surgery was also a contributing factor for 4 of these cancer patients. Although both cancer and surgery are well-known risk VTE factors, clinicians may not appreciate the extremely high risk associated with the combination. Particular effort may be warranted to ensure prophylaxis in this group, and more intensive measures may be necessary.

These results reveal several barriers to the accurate retrospective measurement of preventable inpatient PE. First, the use of discharge diagnoses to monitor the occurrence of inpatient PE is fraught with hazard. In this study, even after excluding patients with a discharge diagnostic code indicating a past history of PE, very few identified patients in fact had an acute or recent event. In addition, many patients were clearly admitted after having the onset of symptoms as outpatients. Further, reliance on discharge diagnoses alone can lead to the inclusion of patients with a presumptive diagnosis made without the advantage of imaging studies or postmortem examination. Although we overcame these barriers through careful record review and strict diagnostic criteria, our results suggest that efficient performance improvement efforts may require ongoing concurrent review.

There are several limitations of this study. First, we excluded PE patients whose diagnoses were made before the third hospital day. Some of these patients may have had events attributable to recent prior hospitalizations and should have received VTE prophylaxis. Second, we considered preventive measures applied at least 24 hours prior to PE to be acceptable evidence of prevention, potentially neglecting prior periods without treatment that might confer increased risk. Bias due to either of these limitations could exaggerate the compliance rates we report. Finally, the retrospective design of this study did not allow for consistent assessments of whether patients had the risk factor of immobility. Nevertheless, immobility was obvious for the 10 patients with PE who had no prior anticoagulation, all of whom had 2 or more risk factors.

Despite an acknowledged need for improvements in clinical practice, past efforts have had mixed results. For instance, in 1 study at a hospital with a well-established EMR, computer alerts led to substantial improvement in the use of preventive measures and in VTE outcomes, but overall compliance remained low. On the other hand, a multidisciplinary approach can achieve marked reductions in preventable VTE events. Key elements of such an approach are a simplified risk assessment tool and concurrent monitoring of patient treatments and outcomes. The Agency for Healthcare Research and Quality has recently published a guide that outlines strategies for achieving “breakthrough levels of improvement” in the prevention of VTE.

In conclusion, this population-based study of hospitalized veterans with PE or at risk for VTE found compliance comparable to rates in published reports. Missed opportunities for prevention included inappropriate and inadequate interventions. Using discharge diagnoses to monitor the occurrence of inpatient PE is of limited value, and efficient
